Appendix B. Descriptions of upland sediment sources and hillslope management problems [1, 2]

Site No.	Location	Subwatershed	Ownership	Description of sediment source and/or hillslope management problem
1	North face Corte Madera Ridge	Larkspur Creek	MCOSD	1999 landslide into Larkspur Creek
2	"Nora's Canyon"; North face Corte Madera Ridge	Larkspur Creek	MCOSD	Active landsliding into Larkspur Creek
3	Southern Marin Line fire road; North face Corte Madera Ridge	Larkspur Creek	MCOSD	Road-cut culverts plug with sediment during storms; road-cut concentrates runoff
4	Blithedale Ridge	Larkspur Creek	MCOSD	Concentrated runoff "shoots off" road-cut
5	Abandoned land development site at end of Cedar Drive	King Mountain Creek	Private	Active gully headcutting
6	MMWD water line under Southern Marin Line fire road	Larkspur Creek	MMWD	Road-cut culverts plug with sediment during storms; road-cut concentrates runoff; slope failures along fire road
7	Windy Ridge; "Evergreen fire road" at top of Baltimore Canyon	Larkspur Creek	MCOSD	Steep, unmaintained fire road, cut in melange; rock-lined ditch clogs with sediment
8	MMWD water line under Pine Mountain Tunnel fire road	San Anselmo Creek	MMWD	Road-cut culverts plug with sediment during storms; landsliding into Carey Camp Creek during 1980s
9	Outlet of Carey Camp Creek	San Anselmo Creek	MCOSD	MCOSD constructed series of check dams at outlet of Carey Camp Creek; filled with sediment in two years
10	San Anselmo Creek nr outlet of Carey Camp Creek	San Anselmo Creek	MCOSD	Ranchers extracted gravel from San Anselmo Creek; MCOSD placed rip-rap bank protection in 1984-85
11	Fire road below ridge dividing Upper San Anselmo and Cascade Creeks	Upper San Anselmo Ck	MMWD	Steep, high-maintenance fire road; water bars necessary
12	Fire road on ridge dividing Upper San Anselmo and Cascade Creeks	Upper San Anselmo Ck	MMWD	Steep,unmaintained fire road; water bars necessary; gullying
13	Fire road; East face White Hill	San Anselmo Creek	MCOSD	Steep, high-maintenance, gullied fire road; cut in greenstone/melange shear zone
14	Middle fire road; Blue Ridge Creek subwatershed; South Face Blue Ridge	San Anselmo Creek	MCOSD	Creek crossings were management problems ten years ago; now maintained
15	Toyon fire road; East face Pams Blue Ridge	San Anselmo Creek	MCOSD	Fire road channelizes runoff; landslide in 1999
16	Gunshot fire road; Sourth face Loma Alta	Fairfax Creek	MCOSD	Fire road gullied
17	Smith Ridge fire road; South face Loma Alta	Fairfax Creek	MCOSD	Fire road gullied; water bar on hillslope above fire road
18	Smith Ridge fire road; South face Loma Alta	Fairfax Creek	MCOSD	Channel head crossing eroding fire road fill; gullying
19	Lewiz Ranch; East face Loma Alta	Sleepy Hollow Creek	Private	Cattle grazing
20	Fire road;	Sleepy Hollow Creek	MCOSD	Numerous active earthflows on ridge; periodic mass wasting
21	Warren Springs Grade Rd; South face of Bald Hill	Ross Creek	MMWD	Ruts concentrate runoff
22	Fire road; East face of Bald Hill	Ross Creek	MMWD	Ruts and in-slope concentrate runoff, frequent blading required
23	Bill Williams Dam; Bill Williams Creek above Phoenix Lake	Ross Creek	MMWD	Reservoir filled with sediment by 1860s; appears stable
24	Fire road crossing; Channel head of north fork Wood Lane Creek	Wood Lane Creek	MMWD	Slope failure along road-cut
25	Uphill from fire road; East face Pilot Knob above Phoenix Lake	Ross Creek	MMWD	Active landsliding
26	Downstream of Phoenix Dam; North face Ross Hill	Ross Creek	MMWD	1982 landslide into Ross Creek
27	Upstream from Deer Park School; North face Bald Hill	Deer Park Creek	MMWD	Hillslope creep into Deer Park Creek
28	Channel headcutting; Sky Ranch Stables	Unsampled Area	Private	Vegetative cover modification and extensive gullying;n greenstone/melange shear zone
29	Fire roads; South face Blue Ridge	San Anselmo Creek	MCOSD	Redundant fire roads
30	Depositional zone at upland-alluvial channel transition; Marin Stables	Wood Lane Creek	MMWD	Channel instability

APPENDIX C
BEDLOAD SEDIMENT TRANSPORT MODELING METHODS

Hydrologists, river engineers, and fishery biologists often need to know the amount of sediment discharge from a river basin. Knowledge of sediment transport in sand-channel streams has been well documented. However, prediction of bedload transport in gravel-bed streams has not been as well documented. Recent research results have developed techniques for prediction of gravel transport. These techniques enable the analyst to estimate gravel transport from hydraulic and sediment data.

SEDCOMP, the program used to analyze the sediment transport for the Corte Madera Creek project, takes cross-section data, and bed material measurements and uses a set of parameters to predict bedload transport past a cross-section. The cross-section and energy slope are used to compute bed shear across the cross-section. The bed shear is the force of the weight of the water on the bed, and the bed shear that moves the bedload. The size distribution of the bed material (either surface layer or subsurface layer, although the subsurface layer was used in this project) is then used to predict the movement of bed material as bedload. Bedload measurements should be used to calibrate the parameters by iterative fitting. However, such measurements were not available for Corte Madera Creek. Therefore, parameters were chosen based on published values and field experience. Once determined, an analysis can be made of the predicted movement of each size class of bed material for each measurement. The parameters in SEDCOMP may then be used with a flow duration curve to compute an annual load.

FEATURES OF SEDCOMP

SEDCOMP is a batch mode program. SEDCOMP predicts bedload transport. SEDCOMP can be used to fit parameters to the algorithm if bedload measurements are available for calibration, it can give a detailed picture of fit by size break for a set of measurements, and it can generate a bedload sediment rating curve by entering a cross-section with various stages.

TECHNICAL BACKGROUND

SEDCOMP computes bedload sediment discharge for a given cross-section on a stream. As with most bedload transport equations, it uses bed shear to estimate transport. Bed shear is the force of the water column on the bed, and is calculated based on the weight of the water and the energy slope of the water. Thus, bed shear is the force of the water along the stream bed. The input data are a cross-section, the energy slope, and bed material size distribution. The energy slope was determined using several cross-sections surveyed in the field, resistance to flow determined by a pebble count of the surface material using the Limerinos equation (1), and the use of the Corps of Engineers standard step-backwater program HEC-2.

The data are analyzed using the Parker and Klingeman procedure (1982), that includes the effect of a "hiding factor"(2). The term 'hiding factor' is used to describe the fact that when there is a mixture of particles on the stream bed, the larger particles hide the smaller particles. Thus, the smaller particles are harder to move than would be predicted by the usual equations based on bed shear, such as that of Meyer-Peter and Mueller. Similarly, because the larger particles project into the flow more than they would if there were uniformly large particles on the bed, larger particles are moved more easily than otherwise predicted. The result is a more uniform movement of particles of all sizes, which is termed "almost equal mobility."

The Parker and Klingeman procedure includes a physically-based semi-empirical equation with two calibration parameters. Those two parameters are: first, a reference critical shear value, TRS50, the shear at which the median diameter of bed material moves, and second, an exponent which relates the shear value required to move any other size present in the bed material to TRS50. The prediction of the size distribution of the bedload is based on the distribution of a parent material. The parent material may be for the pavement material on the bed or the sub-pavement material under the pavement.

Parker and Klingeman's equation 21 is:

$$\frac{\mathrm{TRS(I)}}{\mathrm{TRS50}} = \frac{\mathrm{(DG(I))exp(-PEXP)}}{\mathrm{DMREF}}$$

where TRS(I) is effective shear for size of material DG(I), and TRS50 is the effective shear for the reference size of material, DMREF, the D50 for either the pavement or subpavement material. The exponent, PEXP, and reference Shields stress, TRS50, in the Parker and Klingeman equations 22 and 27 (TRS50 = 0.0876 for subpavement and = 0.035 for pavement material) are related. They also are related to the Wr*, a dimensionless bedload, for which Parker and Klingeman choose 0.002 (p. 1412). The value of 0.002 is a "small but measurable bedload movement" used to determine the reference shear stress, TRS50. If the size is determined by a proper choice of exponent, the volume transported can be fixed by a proper choice of TRS50. This means that with a good set of data the Parker and Klingeman empirical approach can be calibrated for a wide set of conditions.

Determination of a proper "calibrated" reference shear stress depends upon the determination of energy slope. Thus, slope must be known in order for TRS50 to be used to predict the bed load without calibration. Error in determination of the energy slope and the subsurface reference size, D50s, have a similar effect on prediction. If D50s is increased, a change in reference shear, TRS50, must be made to predict with equal accuracy. Thus, both the size distribution of the parent material and energy slope must be accurately determined in order to use the Parker and Klingeman method without calibration. However, if parameters are calibrated to data, the calibrated parameter values will compensate for any errors in measurement of slope and D50, and the resulting parameters may be used to predict bedload movement for that site. For the Corte Madera Creek project pavement and subpavement samples were taken in the field and seived to determine the parent distribution. The energy slope was determined by HEC-2 as described above. The reference shear is the most important parameter in the P-K model for the determination of amount of bedload. The exponent of the relation (PEXP) is most important for determining the size distribution of the bedload. The greater the difference between the median diameter of the parent material (pavement or subpavement) and the bedload, the smaller the exponent must be. The exponent in Parker and Klingeman's Equation 21 must be different from 1.0 (the Parker and Klingeman paper uses 0.982 with the sub-pavement distribution based on their Oak Creek data). The exponent determines how the size distribution of the bedload is related to that of the parent material. A value of 0.95 was used for the Corte Madera Creek project based on field experience in Oregon and Colorado.

The Parker and Klingeman method will predict bedload movement only for those particle sizes contained in the size distribution for the parent material. Therefore, the sample chosen as the parent material must contain some material in all size classes that are contained in the bedload and are to be predicted.

Appendix E. Raw subwatershed channel survey data.

Subwatershed: Deer Park Creek
Location: Fairfax, at d/s end of Deer Park below culvert and above Meerna Rd.
Drainage area:

Date(s) surveyed: 10/9/1999 11/5/1999
Surveyors: Smeltzer Smeltzer
Wheeler Plunkett
Vitomski

Location of notes: 1999 Corte Madera Creek Book
pp. 7-9 pp. 43-47

Benchmarks:

Yellow paint spot on u/s side Meerna Ave above Meerna culvert	100 ft		
Top fire hydrant on Meerna Ave E of Meerna culvert	ft	102.9 ft	
Top of sewer manhole cover on RB below Deer Park culvert	ft	102.475 ft	
		102.36 ft	

Long profile stationing: field: 0.4 ft = d/s end of Deer Park culvert; u/s end of Meerna culvert = ~ 233 ft
Changed in calcs to 0.00 at u/s end of Meerna culvert; 232.4 at d/s end of DP culvert
Data entered on: 11/18/1999 11/24/1999
Data entered by: Smeltzer Smeltzer

Appendix E. Raw subwatershed channel survey data.

Subwatershed: San Anselmo Creek above Wood Lane Creek confluence
Location: u/s Wood Lane Creek confluence, near 430 Bolinas-Fairfax Road, approx. at Al Jones Residence on Cascade Rd

Date(s) surveyed: 11/20/1999
Surveyors: Smeltzer
Ventura
Plunkett

Location of notes: CMC book pp. 68 - 73

Benchmarks: Yellow X on N edge Bolinas-Fairfax road surface between 434 and 430 Bolinas-Fairfax Road 100 ft

Long Profile Stationing: FIELD:arbitrary: STA 0.00 ft, d/s bkf thalweg
CALC: 242.9=0.00, u/s bkf thalweg

Data entered on: 12/2/1999
Data entered by: Smeltzer

Notes: 11/20/99 subsurface sediment sample at ~ STA 175 ft (50 ft)
11/20/99 surface sediment sample at ~ STA 190 ft - STA 150 ft (35-75 ft)

APPENDIX J
METHODOLOGY FOR ASSESSMENT OF THE SUITABILITY OF CANDIDATE SITES FOR IMPLEMENTATION OF INFILTRATION ENHANCEMENT MEASURES

Background

Land use changes within a watershed that decrease retention and infiltration of rainfall can alter streamflow patterns, degrade water quality, and disturb fluvial processes. These physical impacts can result in habitat changes and loss of fish populations (EPA 1997). Section 2 of this report describes the physical impacts of decreased retention and infiltration resulting from historical land use changes within the Corte Madera Creek watershed. The fishery resources condition report (Rich 2000) describes degraded habitat conditions and sparse fish populations that are partially a result of decreased retention and infiltration of rainfall.

Implementing measures on a watershed wide basis to significantly increase on-site retention and infiltration of rainfall would help reduce runoff, lower peak flows in the alluvial network, and help to sustain baseflow during the dry season. The resulting benefits would be improved habitat conditions and, hopefully, increased fish populations. The Bay Area Stormwater Management Agencies Association, which includes MCSPPP, has prepared a document (BASMAA 1999) describing various approaches to increasing retention and infiltration through porous pavement, swales, and other measures. However, retention and infiltration may not be appropriate or effective at all locations due to hydrogeologic conditions or other site constraints. To aid property owners and local municipalities in determining the suitability of a particular site for increased infiltration measures, a screening methodology is presented that should be considered before implementing any specific measure.

Description of Methodology

Soils occurring within the Corte Madera Creek watershed, as mapped, and described in the soil survey of Marin County (USDA/SCS 1978), were evaluated for compatibility with on-site retention and infiltration measures. Most soils were determined to be incompatible due to shallow depth to bedrock, shallow depth to water table, low permeability, or some other limiting factor. Those soils that potentially could be compatible with on-site retention and infiltration included the soil types listed below and delineated in Figure J-1.

- 105 Blucher-Cole complex;
- 202 Urban land-Xerorthents complex;
- 203 Xerorthents, fill; and,
- 204 Xerorthents-Urban land complex.

Sites that lie within the potentially compatible soils areas should be further evaluated for suitability for on-site retention and infiltration measures. The evaluation should consider the following limiting factors:

- Depth to bedrock;

- Depth to the water table;
- Slope stability;
- Proximity to stream channels; and,
- Proximity to basements, underground vaults, retaining walls, or other potentially problematic structures.

Evaluation of these limiting factors should follow these steps:

1. Field check for visual evidence of seasonal high ground-water (mottled soil, wetland vegetation), shallow soils (e.g., bedrock outcrops). If there is evidence of shallow bedrock or a seasonal high ground-water table, then the site should be eliminated from further consideration.

2. Field check for proximity to steep slopes, creek banks or underground structures that would be adversely effected by increase infiltration. If steep slopes, creek banks, or underground structures are identified, then the site should eliminated from further consideration.

3. Drill a 5-foot deep hole, at least 4-6 inches in diameter. During drilling, take soil samples every 1 to 2 feet and place in bags for later examination if needed. Check for impermeable soils, such as tight, clayey soils. Log the soils. Install a 2 to 4-inch plastic perforated pipe-casing with top and bottom caps and backfill with pea-gravel and a cement or clay surface seal. Monitor depth to ground-water during the wet season to check for high ground-water. If clayey soils are present, or if depth to ground-water during the wet season approaches to within about 2 feet of the ground surface, then the site should be eliminated from consideration.

If, after the above steps are completed, no limiting factors are found to occur, then the site should be considered suitable for implementing on-site retention and infiltration measures. It is recommended that the results of the above evaluation be submitted to a licensed engineer or geologist for verification before any measures are implemented.

Possible Candidate Sites for On-Site Retention and Infiltration Measures

The following possible candidate sites lie within the area of compatible soils and could be considered following the above-described methodology:

I. Proposed paved parking lot at San Domenico School, San Anselmo;
II. Possible re-construction of parking lot at Fair-Anselm Plaza, Fairfax;
III. Proposed paved area at the former Ross Hospital; and,
IV. Possible paving of lumberyard at Fairfax Lumber, Fairfax.

APPENDIX K
CONCEPTUAL STREAMBANK STABILIZATION MEASURES FOR A HYPOTHETICAL CASE STUDY

Background

Corte Madera Creek's alluvial channel network became moderately to deeply entrenched in the Holocene valley fill between about 1850 and about 1910. The current channel bed elevation varies between 10 and 20 ft below the abandoned floodplain surface. Observed post-entrenchment channel widening is a natural geomorphic recovery process (Schumm 1999) that can be expected to continue until the channel is wide enough to support an active floodplain. Channel widening is evidenced by chronic channel bank erosion and episodic bank slump failures common throughout the watershed. As a result, a large percentage of the residential, commercial, and municipal property owners bordering the channel network have constructed various bank reinforcement structures. However, by precluding channel widening, bank protection works generally prevent the ongoing natural recovery of the riparian and aquatic habitat. It is a recommendation of this study that projects intended to improve habitat should seek opportunities, where possible, to increase active channel width.

However, as discussed elsewhere, existing residential and commercial structures and associated near-channel land uses (primarily residential back yard lawns and gardens) prevent floodplain restoration or construction at all but a small percentage of the length of the channel network. In instances where existing structures and land uses prevent increasing the active channel width, attempts to reduce bank erosion should employ appropriate streambank stabilization measures that, among other things, do not further reduce existing active channel width. In general, existing channel banks are over-steepened as a result of channel entrenchment. Attempts to reduce bank erosion on steep banks will require less desirable bank treatments (e.g., rock gabions) that support little, if any, riparian vegetation and habitat value. Therefore, projects that consider reducing channel bank slope in order to use more desirable bank treatments (e.g., willow walls and vegetated rock rip-rap) are superior both in long-term stability and ecological value. Reducing channel bank slope without reducing active channel width would require excavation along the top of the terrace bank, which may conflict with existing land uses at many sites. For example, to reduce a typical oversteepened channel bank (bank height 10 ft, slope 80%) to a 1:1 slope would require an excavation 8.2 feet into the top of the bank.

Recommendation

A recommendation of this study is that any future streambank stabilization projects, as far as feasible, will satisfy the following general requirements:

- Floodplain restoration/construction at the site(s) is prevented by existing structures and associated land uses;
- The project does not reduce active channel width (measured from the toe of left bank to the toe of right bank); and,
- The project is part of an integrated streambank stabilization design (as defined below).

An integrated streambank stabilization design will satisfy, at a minimum, the following requirements:

- The project boundaries encompass all of the channel banks (and associated properties) affected by the project, with boundaries defined where possible by existing hydraulic constraints (e.g., bridges);
- The project, if applicable, considers alternative schemes for optimizing the allocation of the various preferred bank treatments (defined below) and channel bank slope reduction along both channel banks in the project reach, and selects the preferred alternative according to ecological, cost, construction feasibility, permitting, and landowner participation and consensus;
- The project retains existing native riparian trees to the extent possible;
- The project employs preferred bank treatments according to existing or post-project channel bank slope (as defined below);
- The project seeks opportunities to reduce the slope of channel banks (by excavating into the top of the bank) in order to use more preferred bank treatments;
- The project does not seek to further reinforce banks stabilized at the toe by existing natural bedrock;
- The project considers the feasibility of removing any existing bank stabilization structures that are not preferred (as defined below); and
- The project prevents elimination of existing physical aquatic habitat features and considers use of anchored small woody debris, where appropriate, to improve aquatic habitat in the project reach;

Typical preferred bank stabilization methods in low to moderate hydraulic energy dissipation zones are as follows:

Steep bank slope (60-90 percent):	Rock gabions; or, Log crib walls.
Moderate bank slope (40-60 percent):	Willow walls with anchored core log at toe of slope; or, Vegetated rock rip-rap below 5-year flood stage with anchored core log at toe of slope, and vegetated filter fabric above 5-year flood stage.
Gradual bank slope (10-40 percent):	Willow walls; or, No stabilization required, remove exotic vegetation and revegetate.

Typical preferred methods in high hydraulic energy dissipation zones are as follows:

Steep bank slope (60-90 percent):	Rock gabions.
Moderate bank slope (40-60 percent):	Vegetated rock rip-rap with revetments at toe of slope.

Gradual bank slope (10-40 percent): Vegetated rock rip-rap with revetments at toe of slope.

Description of Measures

The following are recommended integrated bio-technical streambank stabilization measures for a hypothetical site where near-channel residential and commercial structures and land uses prevent extensive floodplain restoration/construction.

Site Selection

We selected a hypothetical site, approximately 270-ft long, bounded on the upstream and downstream side by existing bridges (Figure K-1). There are existing bank stabilization structures at the site, including a sackcrete wall along the right bank between Cross-section 7 and 8, and vertical flood walls along the right bank between Cross-sections 8 and 9 and along the left bank between Cross-sections 5-9. There is bedrock exposed in the bed and at the toe of the left bank slope between Cross-sections 1 and 2. There are 3 residential properties and 1 commercial property bounding the channel in the project reach.

Project Objectives

The project objectives are to prepare an integrated streambank stabilization plan for the project reach following the recommendations outlined above in this appendix.

Design Methods

We reviewed existing conditions in the reach and prepared 9 Cross-sections referenced to an arbitrary datum to describe channel conditions and overlay recommended design modifications. Figure K-2 shows the recommended bank stabilization measures for Cross-section 3 that typifies the steep, eroding channel banks in the straight between Cross-section 1 and Cross-section 4. Recommended bank treatments include vegetated rip-rap below the 5-year flood stage and anchored toe core-logs along portions of the sub-reach where bank slope can be reduced to about 40-50 percent by excavation into the top of bank (by permission of participating land owners). Vegetated fabric can be used above the 5-year flood stage. Placement of anchored submerged small woody debris under existing cut banks at and near Cross-section 3 is recommended. Terraced rock gabions would be required in the majority of the sub-reach in the absence of these permissions. Rock gabions are also recommended in the hydraulic expansion zone immediately downstream from the bridge. Existing bedrock reinforcement at the toe of the left bank between Cross-section 1 and Cross-section 2 precludes the need for toe reinforcement. Removal of overburden and bank slope reduction is recommended above the bedrock toe reinforcement. Without permission of the landowner, rock gabions are recommended.

Figure K-2 also shows recommended bank treatments at Cross-section 5 that typifies the sub-reach between Cross-section 4 and Cross-section 7. Removal of the floodwall along the left bank is recommended. With landowner permission, excavation into the top of the left bank will be required to achieve moderate bank slopes appropriate for vegetated rock rip-rap bank treatments. The existing land use on the left bank is a commercial storage lot for building materials. The recommended excavated area is presently used only for stockpiling gravel. Buried revetments are specified at the toe of the left bank slope. The right bank in this sub-reach has a gradual slope and low hydraulic energy. Therefore, only exotic vegetation removal and revegetation is recommended (Figure K-2).

Figure K-2 also shows recommended bank treatments for Cross-section 8, near the downstream end of the project reach. Similar to Cross-section 5, removal of the existing flood wall and slope reduction by excavating into the top of the left bank is recommended. The existing land use is the same storage lot. A number of existing redwood trees along the top of the left bank, maximum dbh 1.2 ft, can be removed and transplanted. There are no other current uses of the land on the top of the left bank to be excavated area. Due to the high hydraulic energy dissipation required at the left bank, vegetated rock rip-rap is recommended for the entire 45 percent finished left bank slope, and anchored rock revetments with small woody debris are recommended at the toe. The left bank treatment will transition into steeper rock gabions, or retention of the existing floodwall between Cross-section 8 and Cross-section 9 to allow hydraulic contraction immediately upstream of the bridge. It is recommended that existing bank treatments at the right bank be preserved, in order to preserve a large existing redwood rooted near the top of the bank (Figure K-2).

Design Considerations

This hypothetical case study demonstrates a typical constraint in the Corte Madera Creek watershed. Over-steepened channel banks in moderate and high energy dissipation zones can often not be reliably reinforced with preferred bank treatments (e.g., willow walls, core logs, vegetated bio-fabric, and limited vegetated rock rip-rap) without reducing channel bank slope. Reducing channel bank slope without reducing active channel width (a high priority) entails excavation into the top of the bank (typically 6-9 ft). Although these modifications would allow cooperating land owners to improve the ecological integrity of their banks while building stabilization structures that are more stable and less expensive in the long-run, reducing effective lot size is economically undesirable. The potential for establishing a fund for purchasing an flooding or riparian easement of some sort that would compensate participating land owners for allowing these bank treatments should be examined.

This hypothetical case study emphasizes the necessity of integrating bank stabilization projects so that the project boundaries encompass all of the channel banks (and associated properties) affected by the project, with boundaries defined where possible by existing hydraulic constraints (e.g., bridges). Optimal allocation of bank treatments often does not respect arbitrary property boundary delineations, and deleterious upstream and downstream impacts of ad-hoc projects often outweigh the benefits. Only through effective project boundary and project objectives definition, and cooperation among affected property owners, can sustainable, ecologically beneficial bank stabilization measures be put in place. Through such cooperation is also an opportunity to innovate mechanisms for cost-sharing and public subsidies. Such a cooperative effort could be pursued as a watershed demonstration project.

APPENDIX L
CONCEPTUAL FLOODPLAIN RESTORATION MEASURES FOR A HYPOTHETICAL CASE STUDY

Background

Corte Madera Creek's alluvial channel network became moderately to deeply entrenched in the Holocene valley fill between about 1850 and about 1910, abandoning its pre-entrenchment floodplain. The current channel bed elevation varies between 10 and 20 ft below the abandoned floodplain surface. Throughout the majority of the alluvial channel network, the former floodplain is overtopped only by rare floods, exceeding 50-year and 100-year events. By contrast, an active floodplain is overtopped every 1-5 years. Section 2 of this report attributes channel entrenchment to the effects of historical land use changes in the watershed during the middle and late 1800s. Section 2 also describes loss of riparian habitat and changes in the aquatic habitat due to channel entrenchment.

Observed post-entrenchment channel widening is a natural geomorphic recovery process (Schumm 1999) that can be expected to continue until the channel is wide enough to support an active floodplain. Channel widening is evidenced by chronic channel bank erosion and episodic bank slump failures common throughout the watershed. As a result, a large percentage of the residential, commercial, and municipal property owners bordering the channel network have constructed various bank reinforcement structures. However, by precluding channel widening, bank protection works generally prevent the ongoing natural recovery of the riparian and aquatic habitat.

Recommendation

A recommendation of this study is that projects intended to improve aquatic and riparian habitat and habitat-supporting processes and/or flood control should seek opportunities, where possible, to increase active channel width by:

- eliminating existing bank protection works; and,
- constructing active floodplains flanking the existing channel.

Opportunities for Floodplain Construction

Technically, "floodplain restoration" would entail channel modifications designed to reintroduce frequent flooding onto the former floodplain surface (terrace). This is technically infeasible in the Corte Madera Creek watershed where the former floodplain surface is almost entirely urbanized. Any project intended to introduce an active floodplain to the channel network would therefore entail constructing a new floodplain surface at a design elevation about 4-6 feet above the existing channel bed. The constructed floodplain surface would therefore be about 5-15 feet below the former floodplain surface. Such a "floodplain construction" project would increase the active channel width without increasing frequency of flooding on adjacent properties. In fact, by increasing channel capacity, floodplain construction would locally reduce flooding frequency on the former floodplain.

Opportunities for large-scale floodplain construction in the watershed are limited, as nearly all of the properties adjoining the alluvial channel network have structures constructed close to the channel banks (i.e., within 20-50 ft). Associated land uses, primarily back yard lawns, dominate the narrow strip of the former floodplain remaining along the channel network. There are also limitations on floodplain construction imposed by existing bridge spans upstream and downstream of any given site. In instances where existing structures and land uses prevent increasing the active channel width, attempts to reduce bank erosion should employ appropriate streambank stabilization measures that, among other things, do not further reduce existing active channel width. Appendix K presents recommended streambank stabilization measures for a hypothetical site where near-channel residential and commercial structures and land uses prevent extensive floodplain restoration/construction.

Although nearly all of the properties adjoining the channel network have structures or associated land uses close to the channel banks, there are a number of potential opportunities for large-scale floodplain construction (i.e., constructed floodplain length greater than 500 ft and width greater than 40 ft):

- schools;
- parks and recreation sites;
- parking lots;
- commercial storage yards (lumber yards, etc.);
- redundant streets and off-street parking bordering the channel; and
- clusters of adjacent residential properties without constructions near the channel.

Floodplain construction projects would directly increase functional riparian habitat and improve aquatic habitat benefiting anadromous fish at the project site. It would be necessary to complete a number of projects throughout the watershed in order to substantially increase riparian habitat and improve aquatic habitat enough to anticipate increased salmonid populations. Selection of potential sites, and determining project objectives at each site, should be guided by an understanding of factors limiting the current salmonid population, including potential fish barriers, water quality, summer low-flow, temperature, food, cover, spawning habitat, rearing habitat, etc. Also, the impacts of floodplain construction on the existing riparian habitat should be considered (i.e., removal of existing vegetation on the terrace bank during excavation for floodplain construction).

This study presents a conceptual demonstration floodplain restoration/construction project design for a hypothetical site in the watershed with sufficient undeveloped land adjacent to the channel to construct a floodplain of maximum width 150 ft. In general, the cost of floodplain construction is high, with approximate excavation and hauling costs of about 3-5 dollars per square foot of constructed floodplain. The estimated excavation and hauling cost for the hypothetical case study (Figure L-2) is about $550,000.

Description of Measures

Site Selection

Opportunities and limitations for site selection are described above. We selected a hypothetical case where there is sufficient undeveloped land adjacent to the channel to construct a floodplain along approximately 1,000 ft of the channel with maximum width of about 150 ft (Figure L-2). The hypothetical site is in the middle portion of the watershed, downstream from important summer low-flow season aquatic habitat for the steelhead trout in the upper reaches of the watershed, as identified by Rich (2000).

Project Objectives

We selected the following project objectives for this hypothetical case study:

- Construct an active floodplain that overtops during a 2-year flood and to a depth of no more than 1.5 ft above the active floodplain surface during a 5-year flood;
- Reduce water surface elevation of the 10-year flood by 1 ft;
- Reduce average shear stress on the bed for 2-year, 5-year, and 10-year floods by 50 percent; and,
- Do not cause adverse impacts to water surface elevations and channel bed stability and habitat upstream and downstream from the project boundaries;

Design Measures

We assembled 16 typical cross-sections describing current channel conditions at the site along the project reach, sufficient to build a HEC-RAS hydraulic model of the site. We selected a bankfull elevation profile along the reach based on field indicators, approximately 3.9-4.1 ft above the thalweg elevation profile, to serve as the initial design active floodplain surface elevation. We created design cross-sections simulating excavation of the right bank down to the design active floodplain elevation. We ran 2-year, 5-year, and 10-year floods (discharges determined by apportioning the respective discharges for the Ross gage by drainage area at the site), for pre-project and initial post-project channel geometry. In an iterative process, we edited the active floodplain surface elevation and floodplain width until project objectives were met. Representative existing and design cross-sections (shown on Figure L-2) are shown in Figure L-3.

Design Considerations

The hypothetical case study demonstrates that it is feasible to construct a floodplain that would reduce water surface elevations during the 10-year flood by 1 ft, and reduce shear stress on the bed for a range of flood discharges by more than 50 percent. The case study also emphasizes the necessity to consider possible upstream and downstream impacts of such a project. In particular, project boundaries should be defined as the total extent of project-induced hydraulic change, and cooperation between candidate sites and upstream and downstream properties may be necessary for project success. For example, reduction of water surface elevation at the project site would induce similar reductions extending several hundred feet upstream from the project boundary.

This, in turn, may cause increased flow velocities and local increases on bed and bank shear stress that would offset apparent shear stress reductions predicted by the 1-dimensional model. In some cases, bedrock or concrete structures upstream from the project boundary would prevent channel bed elevation changes, but bank stability upstream from the project boundary may be of concern. Extending the constructed floodplain excavation along the right bank upstream from the project boundaries reflected in Figure L-2 would help offset the effect of local increases in velocity. In general, the upstream and downstream boundaries of constructed floodplains would ideally be situated at natural or infrastructural hydraulic control points, such as existing bridges, check dams, etc.
